

# Big O Notation

Using not-boring math to measure code's efficiency

## The idea behind big O notation

**Big O notation is the language we use for articulating how long an algorithm takes to run.**

It's how we compare the efficiency of different approaches to a problem.

With big O notation we express the runtime in terms of—brace yourself—*how quickly it grows* relative to the input, as the input gets arbitrarily large.

Let's break that down:

**1. how quickly the runtime grows**—Some external factors affect the time it takes for a function to run: the speed of the processor, what else the computer is running, etc. So it's hard to make strong statements about the exact runtime of an algorithm. Instead we use big O notation to express how quickly its runtime grows.

**2. relative to the input**—Since we're not looking at an exact number, we need something to phrase our runtime growth in terms of. We use the size of the input. So we can say things like the runtime grows "on the order of the size of the input" ( $O(n)$ ) or "on the order of the square of the size of the input" ( $O(n^2)$ ).

**3. as the input gets arbitrarily large**—Our algorithm may have steps that seem expensive when  $n$  is small but are eclipsed eventually by other steps as  $n$  gets huge. For big O analysis, we care most about the stuff that grows fastest as the input grows, because everything else is quickly eclipsed as  $n$  gets very large. If you know what an asymptote is, you might see why "big O analysis" is sometimes called "asymptotic analysis."

Big O notation is like math except it's an **awesome, not-boring kind of math** where you get to wave your hands through the details and just focus on what's basically happening.

If this seems abstract so far, that's because it is. Let's look at some examples.

# Big O Notation

Using not-boring math to measure code's efficiency

## Some examples

```
def print_first_item(list_of_items):  
    print list_of_items[0]
```

**This function runs in  $O(1)$  time (or “constant time”) relative to its input.** The input array could be 1 item or 1,000 items, but this function would still just require one “step.”

```
def print_all_items(list_of_items):  
    for item in list_of_items:  
        print item
```

**This function runs in  $O(n)$  time (or “linear time”), where  $n$  is the number of items in the array.** If the array has 10 items, we have to print 10 times. If it has 1,000 items, we have to print 1,000 times.

```
def print_all_possible_ordered_pairs(list_of_items):  
    for first_item in list_of_items:  
        for second_item in list_of_items:  
            print first_item, second_item
```

# Big O Notation

Using not-boring math to measure code's efficiency

Here we're nesting two loops. If our array has  $n$  items, our outer loop runs  $n$  times and our inner loop runs  $n$  times for each iteration of the outer loop, giving us  $n^2$  total prints. **Thus this function runs in  $O(n^2)$  time (or “quadratic time”).** If the array has 10 items, we have to print 100 times. If it has 1,000 items, we have to print 1,000,000 times.

## N could be the actual input, or the size of the input

Both of these functions have  $O(n)$  runtime, even though one takes an integer as its input and the other takes a list:

```
def say_hi_n_times(n):  
    for time in range(n):  
        print "hi"  
  
def print_all_items_in_list(the_list):  
    for item in the_list:  
        print item
```

So sometimes  $n$  is an actual number that's an input to our function, and other times  $n$  is the number of items in an input array (or an input map, or an input object, etc.).

# Big O Notation

## Drop the constants

This is why big O notation *rules*. When you're calculating the big O complexity of something, you just throw out the constants. So like:

```
def print_all_items_twice(the_list):  
    for item in the_list:  
        print item  
  
    # once more, with feeling  
    for item in the_list:  
        print item
```

This is  $O(2n)$ , which we just call  $O(n)$ .

# Big O Notation

Using not-boring math to measure code's efficiency

```
def print_first_item_then_first_half_then_say_hi_100_times(the_list):  
    print the_list[0]  
  
    middle_index = len(the_list) / 2  
    index = 0  
  
    while index < middle_index:  
        print the_list[index]  
        index += 1  
  
    for time in range(100):  
        print "hi"
```

This is  $O(1 + n/2 + 100)$ , which we just call  $O(n)$ .

Why can we get away with this? Remember, for big O notation we're looking at what happens **as  $n$  gets arbitrarily large**. As  $n$  gets really big, adding 100 or dividing by 2 has a decreasingly significant effect.

# Big O Notation

Using not-boring math to measure code's efficiency

## Drop the less significant terms

For example:

```
def print_all_numbers_then_all_pair_sums(list_of_numbers):  
  
    print "these are the numbers:"  
    for number in list_of_numbers:  
        print number  
  
    print "and these are their sums:"  
    for first_number in list_of_numbers:  
        for second_number in list_of_numbers:  
            print first_number + second_number
```

Here our runtime is  $O(n+n^2)$ , which we just call  $O(n^2)$ . Even if it was  $O(n^2/2+100n)$ , it would still be  $O(n^2)$ .

Similarly:

- $O(n^3+50n^2+10000)$  is  $O(n^3)$
- $O((n+30) * (n+5))$  is  $O(n^2)$

Again, we can get away with this because the less significant terms quickly become, well, less significant as  $n$  gets big.

# Big O Notation

## We're usually talking about the “worst case”

Often this “worst case” stipulation is implied. But sometimes you can impress your interviewer by

```
def contains(haystack, needle):  
  
    # does the haystack contain the needle?  
    for item in haystack:  
        if item == needle:  
            return True  
  
    return False
```

Here we might have 100 items in our haystack, but the first item might be the needle, in which case we would return in just 1 iteration of our loop.

In general we'd say this is  $O(n)$  runtime and the “worst case” part would be implied. But to be more specific we could say this is worst case  $O(n)$  and best case  $O(1)$  runtime. For some algorithms we can also make rigorous statements about the “average case” runtime.

# Big O Notation

## Space complexity: the final frontier

Sometimes we want to optimize for using less memory instead of (or in addition to) using less time. Talking about memory cost (or “space complexity”) is very similar to talking about time cost. We simply look at the total size (relative to the size of the input) of any new variables we’re allocating.

This function takes  $O(1)$  space (we aren’t allocating any new variables):

Sometimes the worst case runtime is significantly worse than the best case runtime:

```
def say_hi_n_times(n):  
    for time in range(n):  
        print “hi”
```

$O(n)$  space (the size of hiArray scales with the size of the input):

```
def list_of_hi_n_times(n):  
    hi_list = []  
    for time in range(n):  
        hi_list.append(“hi”)  
    return hi_list
```

# Big O Notation

Using not-boring math to measure code's efficiency

Usually when we talk about space complexity, we're talking about additional space, so we don't include space taken up by the inputs. For example, this function takes constant space even though the input has  $n$  items:

```
def get_largest_item(list_of_items):  
    largest = 0  
    for item in list_of_items:  
        if item > largest:  
            largest = item  
    return largest
```

Sometimes there's a tradeoff between saving time and saving space, so you have to decide which one you're optimizing for.

# Big O Notation

Using not-boring math to measure code's efficiency

## Big O analysis is awesome except when it's not

You should make a habit of thinking about the time and space complexity of algorithms as you design them. Before long this'll become second nature, allowing you to see optimizations and potential performance issues right away.

Asymptotic analysis is a powerful tool, but wield it wisely.

Big O ignores constants, but **sometimes the constants matter**. If we have a script that takes 5 hours to run, an optimization that divides the runtime by 5 might not affect big O, but it still saves you 4 hours of waiting.

**Beware of premature optimization.** Sometimes optimizing time or space negatively impacts readability or coding time. For a young startup it might be more important to write code that's easy to ship quickly or easy to understand later, even if this means it's less time and space efficient than it could be.

But that doesn't mean startups don't care about big O analysis. A great engineer (startup or otherwise) knows how to strike the right balance between runtime, space, implementation time, maintainability, and readability.

**You should develop the skill to see time and space optimizations, as well as the wisdom to judge if those optimizations are worthwhile.**
